On Bijective Encodings of Compressed de Bruijn Terms and Tree-based Number Systems

Paul Tarau

Department of Computer Science and Engineering University of North Texas tarau@cs.unt.edu

Abstract. We introduce a compression mechanism for the de Bruijn representation of lambda terms. In combination with a tree-based number system, we use it for a bijective size-proportionate Gödel numbering scheme that combines into a uniform representation natural number arithmetic with generation and normalization of lambda terms.

Keywords: lambda calculus, de Bruijn indices, lambda term compression, tree-based numbering systems, ranking and unranking of lambda terms, normalization with higher order abstract syntax.

1 Introduction

A joke about the de Bruijn indices representation of lambda terms [1] is that it can be used to tell apart Battlestar Galactica's Cylons from humans. Arguably, the compressed de Bruijn representation that we introduce in this paper is taking this fictional use one step further. To alleviate the legitimate fears of our human readers, this representation will be bijectively mapped to the conventional ones, while simplifying the underlying combinatorial structure of lambda terms. It will also facilitate their (bijective) natural number encodings - known to combinatorialists as ranking / unranking functions and to logicians as Gödel numberings. Such encodings, going back to Ackermann's bijection between natural numbers and hereditarily finite sets [2], are relatively easy to design if one does not care about one side of the bijection exponentially exploding in size. With significant effort, such size-proportionate bijections between term algebras and the set of natural numbers represented with the usual binary notation are defined in [3], using ranking of balanced parentheses languages and a generalization of Cantor's pairing function [4] to tuples. However, the binary search and complex computations involved in the ranking algorithms limit the encoding described in [3] to relatively small terms and numbers not larger than about 2000 bits.

This paper takes a more revolutionary approach. Instead of trying to adjust the bijective Gödel numbering scheme to be size-proportionate, we will replace its target: our natural numbers will be represented as binary trees (a member of the Catalan family of combinatorial objects) on which the usual arithmetic operations will be defined ([5], also submission #82 to this conference.) As a result, encodings of lambda terms, that can be seen as a tree-to-tree transformation, are naturally size-proportionate.

Random lambda terms (and in particular, very large ones) can be useful for testing tools where they play the role of an intermediate language, like compilers for functional languages and proof assistants. Our bijective encoding to tree-based number systems will provide the means to derive an algorithm for the generation of random lambda terms from well-known random generation algorithms for binary trees.

By adding a HOAS-style [6] normal order reducer of our lambda terms and ranking / unranking of simple types, we provide a uniform representation for computations with lambda terms, their types as well as (efficient) arithmetic with possible applications to implementation of domain specific languages, compiler stages and proof assistants relying on lambda terms as their intermediate language.

The paper is organized as follows. Section 2 introduces the compressed de Bruijn terms and bijective transformations from them to standard lambda terms. Section 3 describes mappings from lambda terms to Catalan families of combinatorial objects. These mappings lead to size-proportionate ranking and unranking algorithms for lambda terms and their types. Section 4 describes conversion to/from a HOAS-style representation and gives an algorithm for normal order reduction of lambda terms. Section 5 covers their combinatorial enumeration and section 6 introduces algorithms for generation of random lambda terms. Section 7 discusses related work. Section 8 concludes the paper.

The paper is organized as literate Haskell program. The code in the paper is available at http://www.cse.unt.edu/~tarau/research/2015/XDB.hs, tested with GHC 7.8.3. It defines a module that includes code from submission #82 (file GCcat.hs, available as well from the arXiv draft [5]), which defines arithmetic operations with a tree-based number system. It also includes Haskell library packages needed for the generation of random binary trees.

```
module XDB where
import System.Random
import Math.Combinat.Trees
import GCat
```

To achieve a size-proportionate bijective Gödel numbering scheme, all our arithmetic computations will be performed with members of the type class Cat which provides a generic implementation in terms of members of the Catalan family of combinatorial objects [5], in particular binary or multiway trees.

2 A Compressed Representation of de Bruijn Terms

We will introduce a compressed representation for lambda terms in de Bruijn notation that will facilitate defining a bijection to tree-represented natural numbers.

2.1 De Bruijn Indices

De Bruijn indices [7,8] provide a name-free representation of lambda terms. All terms that can be transformed by a renaming of variables (α -conversion)

will share a unique representation. Variables following lambda abstractions are omitted and their occurrences are marked with positive integers *counting the number of lambdas until the one binding them* is found on the way up to the root of the term.

We represent them using the constructor Ab for application, Lb for lambda abstractions (that we will call shortly *binders*) and Vb for marking the integers corresponding to the de Bruijn indices. This gives the Haskell data type B a as the definition of the de Bruijn terms parameterized by the type a of the indices used by Vb.

```
data B a = Vb a | Lb (B a) | Ab (B a) (B a) deriving (Eq,Show,Read)
```

E.g., the S combinator λx_0 . λx_1 . λx_2 . $((x_0 \ x_2) \ (x_1 \ x_2))$ is represented as Lb (Lb (Lb (Ab (Ab (Vb 2) (Vb 0)) (Ab (Vb 1) (Vb 0)))), corresponding to the fact that Vb 2 is bound by the outermost lambda (three steps away, counting from 0) and the occurrences of Vb 0 are bound each by the closest lambda on the way to the root, represented by the third constructor Lb.

2.2 Compressed de Bruijn terms

Iterated lambdas (represented as a block of constructors Lb in the de Bruijn notation) can be seen as a successor arithmetic representation of a number that counts them. So it makes sense to represent that number in a more efficient numbering system. Note that in de Bruijn notation blocks of lambdas can wrap either applications or variable occurrences represented as indices. This suggests using just two constructors: Vx indicating in a term Vx k n that we have k lambdas wrapped around the de Bruijn index Vb n and Ax, indicating in a term Ax k x y that k lambdas are wrapped around the application Ab x y.

We call the terms built this way with the constructors Vx and Ax compressed de Bruijn terms. They are specified by The Haskell data type X.

For instance, the S combinator Lb (Lb (Ab (Ab (Vb 2) (Vb 0)) (Ab (Vb 1) (Vb 0)))) in de Bruijn notation, will be represented as Ax 3 (Ax 0 (Vx 0 2) (Vx 0 0)) (Ax 0 (Vx 0 1) (Vx 0 0)), with the outermost constructor Ax encoding the three Lb binders and k=0 elsewhere indicating the presence of no lambda binder in (front of) applications Ax k or indices Vx k. Note also that lambda binders counted by k in a leaf term Vx k n can bind at most one variable as no application splits the tree below them.

Open and closed terms Lambda terms might contain *free variables* not associated to any binders. Such terms a called *open*. Any syntactically well formed term of types B and X is an open term. A *closed* term is such that each variable occurrence is associated to a binder. Closed terms can be easily identified by ensuring that the lambda binders on a given path from root outnumber the de Bruijn index of a variable occurrence ending the path.

The function <code>isClosedX</code> checks that a compressed de Bruijn term is closed by trying to find a lambda binding every index on the way up to the root of the lambda tree. The addition operation <code>add</code> and successor function <code>s</code>, defined for instances of the type class <code>Cat</code> will be used to count binders and the comparison operation <code>cmp</code> will ensure that binders on the way down from the root outnumber index values at the leaves of the lambda tree.

```
\begin{array}{l} \text{isClosedX} :: \text{Cat } a \Rightarrow \text{X } a \rightarrow \text{Bool} \\ \text{isClosedX} \ t = f \ t \ e \ \text{where} \\ \text{f (Vx k n)} \ d = \text{LT} = \text{cmp n (add d k)} \\ \text{f (Ax k x y)} \ d = f \ x \ d' \ \&\& \ f \ y \ d' \ \text{where } d' = \text{add d k} \end{array}
```

Example 1 isClosedX on the K combinator $\lambda x_0.(\lambda x_1. x_0)$, written (Vx 2 1) as a compressed de Bruijn term, and a similar small open term. Note the use of both Cat instances N and T parameterizing our (compressed) de Bruijn terms.

```
*XDB> isClosedX (Vx 2 1)
True

*XDB> isClosedX (Vx 2 2)
False

*XDB> isClosedX (Vx (C E (C E E)) (C E E))
True

*XDB> isClosedX (Vx (C E (C E E)) (C E (C E E)))
False
```

2.3 Converting from de Bruijn to compressed de Bruijn terms

The function b2x converts from the usual de Bruijn representation to the compressed one. It proceeds by case analysis on Vb, Ab, Lb and counts the binders Lb as it descends toward the leaves of the tree. Its steps are controlled by the successor function s that increments the counts when crossing a binder.

```
b2x :: (Cat a) \Rightarrow B a \rightarrow X a

b2x (Vb x) = Vx e x

b2x (Ab x y) = Ax e (b2x x) (b2x y)

b2x (Lb x) = f e x where

f k (Ab x y) = Ax (s k) (b2x x) (b2x y)

f k (Vb x) = Vx (s k) x

f k (Lb x) = f (s k) x
```

2.4 Converting from compressed de Bruijn to de Bruijn terms

The function x2b converts from the compressed to the usual de Bruijn representation. It reverses the effect of b2x by expanding the k in V k n and A k x y into k Lb binders (no binders when k=0). The function iterLam performs this operation in both cases, and the predecessor function s, computes the decrements at each step.

```
x2b :: (Cat a) \Rightarrow X a \rightarrow B a

x2b (Vx k x) = iterLam k (Vb x)

x2b (Ax k x y) = iterLam k (Ab (x2b x) (x2b y))

iterLam :: Cat a \Rightarrow a \rightarrow B a \rightarrow B a

iterLam k x | e_k = x
```

Proposition 1 The functions b2x and x2b, having as domains and range open terms, are inverses.

Example 2 The conversion between types B and X of the combinator $Y = \lambda x_0$. ($\lambda x_1.(x_0 (x_1 x_1)) \lambda x_2.(x_0 (x_2 x_1))$

iterLam k x = iterLam (s' k) (Lb x)

This bijection allows borrowing algorithms between the two representations. The function is closedB tests if a term in de Bruijn notation is closed.

```
\begin{array}{l} \mathtt{isClosedB} \ :: \ \mathtt{Cat} \ \mathtt{a} \ \Rightarrow \ \mathtt{B} \ \mathtt{a} \ \rightarrow \ \mathtt{Bool} \\ \mathtt{isClosedB} \ = \ \mathtt{isClosedX} \ \ . \ \mathtt{b2x} \end{array}
```

3 Ranking and Unranking as a Catalan Embedding of Compressed de Bruijn Terms

We will derive an encoding of the compressed de Bruijn terms into objects of type Cat, such that the binary tree instance of type Cat is size-proportionate with the encoded term.

3.1 Ranking compressed de Bruijn terms

The intuition behind the algorithm is that we want leaf nodes of the lambda term to encode into leaves or small trees close to the leaves and application nodes to encode into internal nodes of the binary tree, as much as possible. The function x2t implements such an encoding.

```
x2t :: Cat a \Rightarrow X a \rightarrow a

x2t (Vx k n) | e_ k && e_ n = n

x2t (Vx k n) = c (s' (s' (c (n,k))),e)

x2t (Ax k a b) = c (k,q) where q = c (x2t a,x2t b)
```

Note that leaves $\forall x \ k \ x$ are encoded either as empty leaves of the binary tree or as subtrees with the right branch an empty leaf. To ensure the encoding is bijective, we will need to decrement the result of the constructor c twice, with the predecessor function s. For application nodes $Ax \ k \ a \ b$ we recurse on nodes a and b and then we put the branches together with the constructor c. When c=C this results in a tree of a size proportionate to the compressed de Bruijn term.

3.2 Unranking compressed de Bruijn terms

The decoding function t2x reverses the steps of the encoder x2t. Case analysis on the right branch of the binary tree will tell if it is a leaf node or an internal node of the lambda tree, in which case the shifting, needed for bijectivity, is reversed by applying the successor function s twice before applying the deconstructor c'.

```
t2x :: Cat a \Rightarrow a \rightarrow X a

t2x x | e_ x = Vx x x

t2x z = f y where

(x,y) = c' z

f y | e_ y = Vx k n where (n,k) = c' (s (s x))

f y | c_ y = Ax x (t2x a) (t2x b) where (a,b) = c' y
```

Proposition 2 The functions t2x and x2t, converting between open compressed de Bruijn terms and corresponding instances of Cat, are inverses.

Example 3 The work of t2x and x2t on Cat instance N.

Note however that when using the instance N of Cat which implies the usual binary number representation, the encoding is, as expected, not size proportionate.

This precludes the use of the usual random number generators returning integers in binary notation to generate very large random lambda terms. We will circumvent this problem by using instead an algorithm that (uniformly) generates random binary trees.

We can also define the unranking function t2b and the ranking function b2t for de Bruijn terms, as follows.

```
t2b :: Cat a \Rightarrow a \rightarrow B a

t2b = x2b . t2x

b2t :: Cat a \Rightarrow B a \rightarrow a

b2t = x2t . b2x
```

Proposition 3 The functions t2b and b2t converting between open de Bruijn terms and corresponding instances of Cat, are inverses.

Example 4 The encoding and decoding of the de Bruijn form of the pairing combinator λx_0 . λx_1 . λx_2 .($(x_2 \ x_0) \ x_1$) to ordinary binary numbers and binary trees.

```
*XDB> b2t (Lb (Lb (Lb (Ab (Ab (Vb 0) (Vb 2)) (Vb 1)))))
1389505070847794345082851820104254894239239815\\
            987686768473491008094957555679247
*XDB> t it
C (C (C E E) E) (C
     (C E (C E (C E (C E (C E E))) E))) (C (C E E) E))
*XDB> t2b it
Lb (Lb (Lb (Ab (Vb E)
     (Vb (C E (C E E)))) (Vb (C E E)))))
*XDB> b2t it
C (C (C E E) E) (C (C E (C E (C C E
     (C E (C E E))) E))) (C (C E E) E))
*XDB> n it
1389505070847794345082851820104254894239239815
            987686768473491008094957555679247
*XDB> t2b it
Lb (Lb (Ab (Ab (Vb 0) (Vb 2)) (Vb 1))))
```

To facilitate comparison, it is useful to define the functions sizeT that returns the number of internal node of the binary tree view of a Catalan object and sizeX returning the size of a lambda term in compressed de Bruijn form, in which numeric components k and n are also measured with sizeT.

```
sizeT :: Cat t \Rightarrow t \rightarrow t

sizeT x | e_ x = x

sizeT x = s (add (sizeT a) (sizeT b)) where (a,b) = c' x

sizeX :: Cat a \Rightarrow X a \rightarrow a

sizeX (Vx k n) = add (sizeT k) (sizeT n)

sizeX (Ax k a b) =

s (add (sizeT k) (add (sizeX a) (sizeX b)))
```

Example 5 The sum of the two sizes on an initial segment of \mathbb{N} illustrates the fact that the bijection t2x is indeed size-proportionate.

```
*Main> sum (map (sizeT) [0..10000])
114973
*Main> sum (map (sizeX.t2x) [0..10000])
75288
```

Proposition 4 The average time complexity of t2b and b2t is O(n) for input size n and their worst case time complexity is $O(n \log^*(n))$ when working on instance T (binary trees).

Proof. It follows from the fact that the average complexity of c, c, s and s, is constant time, the worst case complexity of s and s, is $O(log^*(n))$ and at O(n) of these are performed by t2b and b2t.

3.3 Conversion to/from a canonical representation of lambda terms with integer variable names

We represent standard lambda terms [9] by using the constructors Ls for lambda abstractions, As for applications and Vs for variable occurrences.

```
data S a = Vs a \mid Ls a (S a) \mid As (S a) (S a)
deriving (Eq,Show,Read)
```

The function b2s converts from the de Bruijn representation to lambda terms whose canonical names are provided by natural numbers. We will call them terms in *standard notation*.

```
b2s :: Cat a ⇒ B a → S a
b2s a = f a e [] where
f :: (Cat a) ⇒ B a → a → [a] → S a
f (Vb i) _ vs = Vs (at i vs)
f (Lb a) v vs = Ls v (f a (s v) (v:vs))
f (Ab a b) v vs = As (f a v vs) (f b v vs)

at i (x:_) | e_ i = x
at i (_:xs) = at (s' i) xs
```

Note the use of the helper function at that associates to an index i a variable in position i on the list vs. As we initialize in b2s when calling helper function f the list of index variables to [], we enforce that only closed terms (having no free variables) are accepted.

The inverse transformation is defined by the function s2b.

```
s2b :: Cat a \Rightarrow S a \rightarrow B a

s2b x = f x [] where

f :: Cat a \Rightarrow S a \rightarrow [a] \rightarrow B a

f (Vs x) vs = Vb (at x vs)

f (As x y) vs = Ab (f x vs) (f y vs)

f (Ls v y) vs = Lb a where a = f y (v:vs)
```

Note again the use of at, this time to locate the index i on the list of variables vs. By initializing vs with [] in the call to helper function f, we enforce that only closed terms are accepted.

Proposition 5 The functions s2b and b2s, converting between closed de Bruijn terms and closed standard terms, are inverses.

Example 6 The bijection defined by the functions s2b and b2s on the term $\lambda x_0.(\lambda x_1.(x_0\ (x_1\ x_1))\ \lambda x_2.(x_0\ (x_2\ x_2))).$

4 HOAS-style Normalization with Tree-based Arithmetic Operations

We will now describe a (Turing-complete) evaluation mechanism for closed lambda terms, called normal order reduction [10]. A mapping between de Bruijn terms and a new data type that mimics standard lambda terms, except for representing binders as functions in the underlying implementation language, will be used both ways to evaluate and then return the result as a de Bruijn term.

4.1 Representing lambdas as functions in the implementation language

The data type H represents leaves Vh of the lambda tree and applications Ah the same way as the standard lambda terms of type S. However, lambda binders, meant to be substituted with terms during β -reduction steps are represented as functions from the domain H to itself.

```
data H a = Vh a | Lh (H a 	o H a) | Ah (H a) (H a)
```

4.2 The HOAS-style Normal Order Reducer

Normal order evaluation [10] ensures that if a normal form exists, it is found after a finite number of steps. For instance, simply typed lambda terms are strongly normalizing - a normal form exists for every well-typed term. In lambda-calculus based functional languages computing a normal form, normalization can be achieved through a HOAS (Higher-Order Abstract Syntax) mechanism, that borrows the substitution operation from the underlying "meta-language". To this end, lambdas are implemented as functions which get executed (usually lazily) when substitutions occur. We refer to [6] for the original description of this mechanism, widely used these days for implementing embedded domain specific languages and proof assistants in languages like Haskell or ML.

The function **nf** implements normalization of a term of type H, derived from a closed de Bruijn term. At each normalization step, when encountering a binder of the form Lh f, the normalizer **nf** traverses it and it is composed with f. At each application step Ah f a, if the left branch is a lambda, it is applied to

the reduced form of the right branch, as implemented by the helper function h. Otherwise, the application node is left unchanged.

```
\begin{array}{lll} \text{nf} & :: \text{H a} \rightarrow \text{H a} \\ \text{nf} & (\text{Vh a}) = \text{Vh a} \\ \text{nf} & (\text{Lh f}) & = \text{Lh (nf . f)} \\ \text{nf} & (\text{Ah f a}) = \text{h (nf f) (nf a) where} \\ \text{h} & :: \text{H a} \rightarrow \text{H a} \rightarrow \text{H a} \\ \text{h} & (\text{Lh g}) & x = \text{g x} \\ \text{h g x} & = \text{Ah g x} \end{array}
```

The result of implementing lambdas as functions is that we not only borrow substitutions from the underlying Haskell system but also the underlying (normal) order of evaluation.

4.3 Closed terms to/from HOAS

Conversion from the type H to the type B is quite similar to conversion from B to standard terms S. Like the function s2b, the function h2b traverses application nodes. As in the case of our other transformers, the (simple) numerical computations involved in the transformations will be performed using the arithmetic on Catalan objects of type Cat.

```
h2b :: Cat a \Rightarrow H \ a \rightarrow B \ a
h2b t = h e t where
h d (Lh f) = Lb (h d' (f (Vh d'))) where d' = s d
h d (Ah a b) = Ab (h d a) (h d b)
h d (Vh d') = Vb (sub d d')
```

```
b2h :: Cat a \Rightarrow B a \rightarrow H a

b2h t = h t [] where

h :: Cat a \Rightarrow B a \rightarrow [H a] \rightarrow H a

h (Lb a) xs = Lh (\lambda x \rightarrow h a (x:xs))

h (Ab a b) xs = Ah (h a xs) (h b xs)

h (Vb i) xs = at i xs
```

Example 7 Testing that h2b is a left inverse of h2b.

```
*XDB> (h2b . b2h) (Lb (Lb (Lb (Ab (Ab (Vb 0) (Vb 2)) (Vb 1))))
Lb (Lb (Lb (Ab (Ab (Vb 0) (Vb 2)) (Vb 1))))
```

While so called "exotic terms" are possible in the data type H to which no terms of type B correspond, the terms brought to the H side by b2h and back by h2b are identical.

4.4 Evaluating closed lambda terms

As our normal order reduction is is borrowed via a HOAS mechanism from the underlying Haskell system, evaluation is restricted to closed terms. Instead of getting help form a Maybe type, it is simpler to define its result as the trivial open term Vb e for all open terms.

We obtain a normal order reducer for de Bruijn terms by wrapping up nf with the transformers b2h and h2b.

```
evalB :: (Cat a) \Rightarrow B a \rightarrow B a evalB x | isClosedB x = (h2b .nf . b2h) x evalB _ = Vb e
```

We can then lend the evaluator also to compressed de Bruijn terms.

```
evalX :: (Cat a) \Rightarrow X a \rightarrow X a evalX x = (b2x . evalB . x2b) x
```

Example 8 Reduction to the identity $I = \lambda x_0.x_0$ of $SKK = ((\lambda x_1. \lambda x_1. \lambda x_2. ((x_0 \ x_2) \ (x_1 \ x_2)) \ \lambda x_3. \lambda x_4.x_3) \ \lambda x_5. \lambda x_6.x_5)$ in compressed de Bruijn notation.

```
*XDB> evalX (Ax 0 (Ax 0 (Ax 3 (Ax 0 (Vx 0 2) (Vx 0 0)) (Ax 0 (Vx 0 1) (Vx 0 0))) (Vx 2 1)) (Vx 2 1))

Vx 1 0
```

4.5 Catalan objects as lambda terms

Given the bijection between instances of the Catalan family, we can go one step further and extend the evaluator to binary trees.

```
\begin{array}{l} \text{evalT} \ :: \ T {\rightarrow} T \\ \text{evalT} \ = \ x2 \text{t} \ . \ \text{evalX} \ . \ \text{t2x} \end{array}
```

As we have also made the usual natural numbers members of the Catalan family, we can define normal order reduction of such "arithmetized" lambda terms as the arithmetic function evalN.

```
\begin{array}{lll} \mathtt{evalN} & :: & \mathtt{N} {\rightarrow} \mathtt{N} \\ \mathtt{evalN} & = & \mathtt{x2t} & . & \mathtt{evalX} & . & \mathtt{t2x} \end{array}
```

Example 9 Evaluation of binary trees and natural numbers seen as lambda terms.

```
*XDB> evalT (C (C E (C E E)) (C (C E E) E))
C (C (C E E) E) E

*XDB> filter (>0) (map evalN [0..31])
[1,4,8,1,11,1,15,16,15,20,23,15,28,31]
```

As evaluation is Turing-complete, these functions are not total. For instance, evalN 318, corresponding to the lambda term $\omega = (\lambda x.(x\ x))(\lambda x.(x\ x))$, is non-terminating.

5 Generation of simple types and lambda terms

Given the size-proportionate bijection between open lambda terms and Catalan objects, we can use generators for the later to generate the former.

5.1 Ranking and unranking simple types

Simple types with one base type O are binary trees defined by the data type ST, built with the right associative arrow constructor :->.

```
\begin{array}{ll} \text{infixr 5} : \rightarrow \\ \text{data ST} = 0 \hspace{0.1cm} | \hspace{0.1cm} \text{ST} : \rightarrow \hspace{0.1cm} \text{ST deriving (Eq,Read,Show)} \end{array}
```

We can make simple types an instance of the Catalan family of combinatorial objects Cat, as follows.

```
instance Cat ST where
e = 0
c (x,y) = (x:\rightarrow y)
c' (x:\rightarrow y) = (x,y)
```

We specialize view to provide the bijection st from any other member of the family, to ST.

```
\begin{array}{l} \mathtt{st} \, :: \, \mathtt{Cat} \, \, \mathtt{a} \, \Rightarrow \, \mathtt{a} {\rightarrow} \mathtt{ST} \\ \mathtt{st} \, = \, \mathtt{view} \end{array}
```

At this point, "ranking" is just the application of st to any other instance of Cat, in particular N.

Example 10 Ranking and unranking of simple types to natural numbers of type N

```
*XDB> st 42
0 :-> (0 :-> (0 :-> (0 :-> (0 :-> 0)))))
*XDB> n it
```

Note that in this case "unranking" is provided by the inverse bijection ${\tt n}$ from N to ST.

Example 11 Using the function st to generate simple types via unranking from natural numbers.

```
*XDB> mapM_ print (map st [0..7])
0
0 :-> 0
0 :-> 0
0 :-> 0
0 :-> 0 :-> 0
(0 :-> 0) :-> 0
(0 :-> 0) :-> 0
0 :-> (0 :-> 0)
0 :-> (0 :-> 0) :-> 0)
0 :-> ((0 :-> 0) :-> 0)
(0 :-> ((0 :-> 0) :-> 0)
```

5.2 A generator for Catalan objects

The function genCat implements a simple generator for Catalan objects with a fixed number of internal nodes. Note that computations are expressed in terms of the arithmetic operations on type Cat.

```
\begin{array}{lll} \operatorname{genCat} & :: \operatorname{Cat} \ t \Rightarrow t \to [t] \\ \operatorname{genCat} \ n & \mid e_{-} \ n = [n] \\ \operatorname{genCat} \ n & \mid c_{-} \ n = [ \\ & c \ (x,y) & \mid k \leftarrow \operatorname{nums} \ (s' \ n), \\ & & \times \leftarrow \operatorname{genCat} \ k, \\ & & y \leftarrow \operatorname{genCat} \ (s' \ (\operatorname{sub} \ n \ k)) \\ \end{array} \right] \end{array}
```

Example 12 Generation of simple types with exactly 3 arrows and their natural number encodings.

```
*XDB> mapM_ print (genCat (st 3))
0 :-> (0 :-> (0 :-> 0))
0 :-> ((0 :-> 0) :-> 0)
(0 :-> (0 :-> 0) :-> 0)
(0 :-> (0 :-> 0) :-> 0
((0 :-> 0) :-> 0) :-> 0

*XDB> genCat 3
[5,6,4,7,15]
```

Given that closed terms have interesting uses in random testing we derive generators for them in compressed de Bruijn and de Bruijn form.

```
\begin{array}{lll} \texttt{genCatX} & :: \texttt{Cat} \ \texttt{a} \Rightarrow \texttt{a} \to \texttt{[X a]} \\ \texttt{genCatX} & = \texttt{filter} \ \texttt{isClosedX} \ . \ \texttt{map} \ \texttt{t2x} \ . \ \texttt{genCat} \\ \\ \texttt{genCatB} & :: \texttt{Cat} \ \texttt{a} \Rightarrow \texttt{a} \to \texttt{[B a]} \\ \texttt{genCatB} & = \texttt{filter} \ \texttt{isClosedB} \ . \ \texttt{map} \ \texttt{t2b} \ . \ \texttt{genCat} \\ \end{array}
```

Example 13 Generation of closed compressed de Bruijn terms decoded from binary trees with 3 internal nodes.

```
*XDB> mapM_ print (genCatX 4)
Ax 0 (Vx 1 0) (Vx 1 0)
Ax 1 (Vx 0 0) (Vx 1 0)
Ax 1 (Vx 1 0) (Vx 0 0)
Ax 2 (Vx 0 0) (Vx 0 0)
Ax 3 (Vx 0 0) (Vx 0 0)
Vx 3 0
Vx 4 0
Vx 8 0
```

5.3 Generation of lambda terms via unranking

While direct enumeration of terms constrained by number of nodes or depth is straightforward in Haskell (as illustrated by function genCat), an unranking algorithm is also usable for generation of large terms, including generation of very large random terms.

Generating open terms in compressed de Bruijn form Open terms are generated simply by iterating over an initial segment of \mathbb{N} with the function t2x.

Reusing unranking-based open term generators for more constrained families of lambda terms works when their asymptotic density is relatively high. Fortunately we know from the extensive quantitative analysis available in the literature [11–13] when this is the case.

The function genClosedX generates closed terms by filtering the results of genOpenX with the predicate isClosedX.

```
genClosedX 1 = filter isClosedX (genOpenX 1)
```

Example 14 Generation of closed compressed de Bruijn terms. Note the more than 50% closed terms among the first 10000 open terms.

```
*XDB> genClosedX 8
[Vx 1 0,Ax 1 (Vx 0 0) (Vx 0 0),Ax 2 (Vx 0 0) (Vx 0 0)]

*XDB> map x2t (genClosedX 30)
[1,4,8,9,11,12,15,16,19,20,23,24,28]

*XDB> length (genClosedX (t 10000))
5375
```

6 Random generation of lambda terms and simple types via unranking

As the ranking bijection of the compressed de Bruijn lambda terms maps them to Catalan objects, we can use unranking of uniformly generated random binary trees to generate random terms.

6.1 Generating random binary trees and simple types

We will rely on the Haskell library Math.Combinat.Trees to generate binary trees uniformly, using a variant of Rémy's algorithm described in [14], as well as Haskell's built-in random generator from package System.Random. This will allow generation of random lambda terms corresponding to super-exponentially

sized numbers of type N, but size-proportionate when natural numbers are represented by the binary trees of type T.

The function ranCat is parametrized by the function tf that picks a type for a leaf among the instances of Cat, to be propagated as the type of tree, as well as the size of the tree and the random generator g.

```
ranCat :: (Cat t, RandomGen g) \Rightarrow
(N \to t) \to Int \to g \to (t, g)
ranCat tf size g = (bt2c \ bt,g') where
(bt,g') = randomBinaryTree \ size \ g
bt2c \ (Leaf \ ()) = tf \ 0
bt2c \ (Branch \ 1 \ r) = c \ (bt2c \ 1,bt2c \ r)
```

The function ranCat1 allows getting a random tree of a given size and type, by giving a seed that initializes the random generator **g**.

```
ranCat1 tf size seed =
  fst (ranCat tf size (mkStdGen seed))
```

Example 15 We will illustrate the generation of random binary trees by using the instance ST of Cat, resulting in random simple types represented as binary trees.

```
*XDB> ranCat1 st 5 42 ((0 :-> 0) :-> (0 :-> 0)
```

6.2 Generating random compressed de Bruijn terms

We will use the bijection t2x from Catalan objects to open compressed de Bruijn trees, parameterized by the function tf that picks the type of the instance of Cat to be used.

The function ranOpenX generates random terms in a way similar to the function ranCat.

```
ranOpenX tf size g = (t2x r,g') where (r,g') = ranCat tf size g
```

The function ${\tt ranOpen1X}$ generates random terms given a seed for the random generator.

```
ranOpen1X tf size seed = t2x (ranCat1 tf size seed)
```

The function ranClosedX filters the generated terms until a closed one is found.

```
\label{eq:ranClosedX} \begin{array}{l} \text{ranClosedX tf size g} = \\ \text{if isClosedX x then x else ranClosedX tf size g' where} \\ \text{(a,g')} = \text{ranCat tf size g} \\ \text{x} = \text{t2x a} \end{array}
```

The function ${\tt ranClosed1X}$ works in a similar way, except for providing a ${\tt seed}$ instead of a random generator.

```
\label{eq:constraints} \begin{array}{l} {\tt ranClosed1X~tf~size~g~where} \\ {\tt g=mkStdGen~seed} \end{array}
```

Example 16 Generation of some random lambda terms (including very large ones) in compressed de Bruijn form.

```
*XDB> ranClosed1X n 3 9
Ax 1 (Vx 0 0) (Vx 0 0)

*XDB> ranClosed1X t 3 9
Ax (C E E) (Vx E E) (Vx E E)

*XDB> n (sizeX (ranClosed1X t 100 9))

96

*XDB> n (sizeX (ranOpen1X t 50000 42))

50001
```

7 Related work

Originally introduced in [7], the de Bruijn notation makes terms equivalent up to α -conversion and facilitates their normalization [8]. As indices replace variable names by their stack-order relative positioning to their binders, they are already more compact than standard lambda terms. However as iteration of their lambda binders can be seen as a form of unary Peano arithmetic, it made sense to further compress them by counting the binders more efficiently. While this looks like a very obvious idea, we have not seen it in the literature, despite of an extensive search effort.

Combinatorics of lambda terms, including enumeration, random generation and asymptotic behavior has seen an increased interest recently (see for instance [12, 15, 11, 13, 16]), partly motivated by applications to software testing given the widespread use of lambda terms as an intermediate language in compilers for functional languages and proof assistants.

Ranking and unranking of lambda terms can be seen as a building block for bijective serialization of practical data types [17, 18] as well as for Gödel numbering schemes of theoretical relevance. In fact, ranking functions for sequences can be traced back to Gödel numberings [19, 20] associated to formulas.

8 Conclusion and future work

We have provided a fresh look at several aspects of the representation, encoding, combinatorial generation of lambda terms, with focus on their de Bruijn form and a compressed variant of it.

Our computations have used a type class defining generic arithmetic operations on members of the Catalan family of combinatorial objects. They have served in implementing bijections between representations of terms, combinatorial generation and conversion to/from HOAS-like form used for normalization of lambda terms. Some interesting synergies have been triggered by this combination of apparently heterogeneous techniques:

- we have provided a simple size-proportionate bijective encoding of compressed De Bruiin terms to our tree-based "natural numbers"
- the same "natural numbers" (actually operated on through a binary tree perspective on Catalan objects), have served to do routine arithmetic operations, with average complexity comparable to the usual binary numbers
- the use of tree-based numbers, a target for ranking/unranking of lambda terms and a uniform random generation algorithm for binary trees, have enabled generation of (possibly very large) random open lambda terms

We have not approached yet some of the remaining hard problems related to uniform random generation of more "realistic" lambda terms appearing in compilers and proof assistants e.g. well-typed and closed terms, for which no linear-time algorithms are known. The techniques, involving binary search, based on ordinary binary numbers for either term algebras in [3] or closed lambda terms in [11] will require more work to adapt to possibly linear algorithms based on our size-proportionate encodings in a tree-based numbering system. Also, an empirical study of the shapes and distribution of frequent lambda term patterns appearing in written and generated code is likely to be useful to fine-tune ranking/unranking algorithms better suited for random generation of such terms.
